A search for light sterile neutrino mixing was performed with the first 217 days of data from the Daya Bay Reactor Antineutrino Experiment. The experiment’s unique configuration of multiple baselines from six 2.9 GWth nuclear reactors to six antineutrino detectors deployed in two near (effective baselines 512 m and 561 m) and one far (1579 m) underground experimental halls makes it possible to test for oscillations to a fourth (sterile) neutrino in the $10^{-3}$ eV$^2 < |\Delta m^2_{41}| < 0.3$ eV$^2$ range. The relative spectral distortion due to electron antineutrino disappearance was found to be consistent with that of the three-flavor oscillation model. The derived limits on $\sin^2 2\theta_{41}$ cover the $10^{-3}$ eV$^2 < |\Delta m^2_{41}| < 0.1$ eV$^2$ region, which was largely unexplored.

Measurements in the past decades have revealed large mixing between the flavor and mass eigenstates of neutrinos. The neutrino mixing framework [1–3] with three flavors has been successful in explaining most experimental results, and several-percent precision has been attained in the determination of the neutrino mixing angles and the mass splittings. Despite this great progress, there is still room for other generations of the neutrino mixing angles and the mass splittings. Despite this progress, there is still room for other generations of the neutrino mixing angles and the mass splittings. If $\nu$ or $\nu_e$ flux took into account the daily livetime-corrected thermal power, the fission fractions of each isotope as provided by the reactor company, the fission energies, and the number of antineutrinos produced per fission per isotope [47].

The precision of the measured baselines was about 2 cm with both the GPS and Total Station [48]. The geometric effect due to the finite size of the reactor cores and the antineutrino detectors, whose dimensions are comparable to the oscillation length at $|\Delta m^2| \sim 3 eV^2$, was assessed by assuming that antineutrinos were produced and interacted uniformly in these volumes. The impact was found to be unimportant in the range of $|\Delta m^2|$ where Daya Bay is most sensitive ($|\Delta m^2| < 0.3 eV^2$). Higher order effects, such as the non-uniform production of antineutrinos inside the reactor cores due to a particular reactor fuel burning history, also had a negligible impact on the final result.

The Daya Bay experiment has two near underground experimental halls (EH1 and EH2) and one far hall (EH3). Each hall houses functionally identical, three-zone antineutrino detectors (ADs) submerged in pools of ultra-pure water segmented into two optically decoupled regions. The water pools are instrumented with photomultiplier tubes (PMTs) to tag cosmic-ray-induced interactions. Reactor antineutrinos were detected via the inverse $\beta$-decay (IBD) reaction ($\nu_e + p \rightarrow e^+ + n$). The coincidence of the prompt ($e^+$ ionization and annihilation) and delayed ($n$ capture on Gd) signals efficiently suppressed the backgrounds, which amounted to less than 2% (5%) of the entire candidate samples in the near (far) halls [45]. The prompt signal measured the $\nu_e$ energy with an energy resolution $\sigma_E/E \approx 8\%$ at 1 MeV. More details on the reconstruction and detector performance can be found in Ref. [46]. A summary of the IBD candidates used in this analysis, together with the baselines of the three experimental halls to each pair of reactors, is shown in Table I.

The uncertainty in the absolute energy scale of positrons was estimated to be about 1.5% through a combination of the uncertainties of calibration data and various energy models [45]. This quantity had a negligible effect on the sensitivity of the sterile neutrino search due to the relative nature of the measurement with functionally identical detectors. The uncertainty of the relative energy scale was determined from the relative response of all ADs to various calibration sources that spanned the IBD positron energy range, and was found to be 0.35%. The predicted $\nu_e$ flux took into account the daily livetime-corrected thermal power, the fission fractions of each isotope as provided by the reactor company, the fission energies, and the number of antineutrinos produced per fission per isotope [47].

The impact was found to be unimportant in the range of $|\Delta m^2|$ where Daya Bay is most sensitive ($|\Delta m^2| < 0.3 eV^2$). Higher order effects, such as the non-uniform production of antineutrinos inside the reactor cores due to a particular reactor fuel burning history, also had a negligible impact on the final result.

![FIG. 1. (color online) Prompt energy spectra observed at EH2 (top) and EH3 (bottom), divided by the prediction from the EH1 spectrum with the three-neutrino best fit oscillation parameters from the previous Daya Bay analysis [45]. The gray band represents the uncertainty of three-neutrino oscillation prediction, which includes the statistical uncertainty of the EH1 data and all the systematic uncertainties. Predictions with $\sin^2 2\theta_{14} = 0.1$ and two representative $|\Delta m^2|_{31}$ values are also shown as the dotted and dashed curves.](image-url)
The three halls, in a fashion similar to what was described in the recent Daya Bay spectral analysis [45]. A binned log-likelihood method was adopted with nuisance parameters constrained with the detector response and the backgrounds, and with a covariance matrix encapsulating the reactor flux uncertainties as given in the Huber [49] and Mueller [39] flux models. The rate uncertainty of the absolute reactor $\nu_e$ flux was enlarged to 5% based on Ref. [40]. The fit used $\sin^2 2\theta_{12} = 0.857 \pm 0.024$, $\Delta m^2_{21} = (7.50 \pm 0.20) \times 10^{-5}$ eV$^2$ [50] and $|\Delta m^2_{14}| = (2.41 \pm 0.10) \times 10^{-3}$ eV$^2$ [51]. The values of $\sin^2 2\theta_{13}$, $\sin^2 2\theta_{14}$ and $|\Delta m^2_{41}|$ were unconstrained. For the 3+1 neutrino model, a global minimum of $\chi^2_{3\nu}/NDF = 158.8/153$ was obtained, while the minimum for the three-neutrino model was $\chi^2_{3\nu}/NDF = 162.6/155$. We used the $\Delta \chi^2 = \chi^2_{3\nu} - \chi^2_{4\nu}$ distribution obtained from three-neutrino Monte Carlo samples that incorporated both statistical and systematic variations to obtain a p-value [52] of 0.74 for $\Delta \chi^2 = 3.8$. The data were thus found to be consistent with the three-neutrino model, and there was no significant evidence for sterile neutrino mixing.

The second analysis performed a purely relative comparison between data at the near and far halls. The observed prompt energy spectra of the near halls were extrapolated to the far hall and compared with observation. This process was done independently for each prompt energy bin, by first unfolding it into the corresponding true antineutrino energy spectrum and then extrapolating to the far hall based on the known baselines and the reactor power profiles. A covariance matrix, generated from a large Monte Carlo dataset incorporating both statistical and systematic variations, was used to account for all uncertainties. The resulting p-value was 0.87. More details about this approach can be found in Ref. [53].

The third analysis exploited both rate and spectral information in a way that is similar to the first method but using a covariance matrix. This matrix was calculated based on standard uncertainty propagation methods, without an extensive generation of Monte Carlo samples. The obtained p-value was 0.74.

The various analyses have complementary strengths. Those that incorporated reactor antineutrino flux constraints had a slightly higher reach in sensitivity, particularly for higher values of $|\Delta m^2_{41}|$. The purely relative analysis was more robust against uncertainties in the predicted reactor antineutrino flux. The different treatments of systematic uncertainties provided a thorough cross-check of the results, which were found to be consistent for all the analyses in the region where the relative spectral measurement dominated the sensitivity ($|\Delta m^2_{41}| < 0.3$ eV$^2$). As evidenced by the reported p-values, no significant signature for sterile neutrino mixing was found by any of the methods.

Two methods were adopted to set the exclusion limits in the $(|\Delta m^2_{41}|, \sin^2 2\theta_{14})$ space. The first one was a frequentist approach with a likelihood ratio as the ordering principle, as proposed by Feldman and Cousins [54]. For each point $\eta \equiv (|\Delta m^2_{41}|, \sin^2 2\theta_{14})$, the value $\Delta \chi^2 (\eta)$ encompassing a fraction $\alpha$ of the events in the $\chi^2 (\eta) - \chi^2 (\eta_{\text{best}})$ distribution was determined, where $\eta_{\text{best}}$ was the best-fit point.

![FIG. 2. (color online) Comparison of the 95% CLs sensitivities (see text for details) for various combinations of the EH's data. The sensitivities were estimated from an Asimov Monte Carlo data set that was generated without statistical nor systematic variations. All the Daya Bay sensitivity curves were calculated assuming 5% rate uncertainty in the reactor flux except the dot-dashed one, which corresponds to a comparison of spectra only. Normal mass hierarchy was assumed for both $\Delta m^2_{31}$ and $\Delta m^2_{41}$. The dip structure at $|\Delta m^2_{31}| \approx 2.4 \times 10^{-3}$ eV$^2$ was caused by the degeneracy between $\sin^2 2\theta_{14}$ and $\sin^2 2\theta_{13}$. The green dashed line represents Bugey’s [32] 90% C.L. limit on $\nu_e$ disappearance and the magenta double-dot-single-dashed line represents the combined KARMEN and LSND 95% C.L. limit on $\nu_e$ disappearance from $\nu_e$-carbon cross section measurements [33].](image-url)
This distribution was obtained by fitting a large number of simulated experiments that included statistical and systematic variations. To reduce the number of computations, the simulated experiments were generated with a fixed value of \( \sin^2 2\theta_{13} = 0.09 \) [45], after it was verified that the dependency of \( \Delta \chi^2(\eta) \) on this parameter was negligible. The point \( \eta \) was then declared to be inside the \( \alpha \) C.L. acceptance region if \( \Delta \chi^2_{\text{data}}(\eta) < \Delta \chi^2(\eta) \). The 95% confidence level contour from the Feldman-Cousins method and the 95% CLs method exclusion contour are shown in Fig. 3. The two methods gave comparable results. The detailed structure is due to the finite statistics of the data. The impact of varying the bin size of the IBD prompt energy spectrum from 200 keV to 500 keV was negligible. Moreover, the choice of mass ordering in both the three- and four-neutrino scenarios had a marginal impact on the results. For comparison, Bugey’s 90% C.L. exclusion on \( \nu_e \) disappearance obtained from their ratio of the positron energy spectra measured at 40/15 m [32] is also shown. Our result presently provides the most stringent limits on sterile neutrino mixing at \(|\Delta m^2_{41}| < 0.1 \text{ eV}^2\) using the electron antineutrino disappearance channel. This result is complementary to those from the \( \nu_\mu \rightarrow \nu_e \) and \( \bar{\nu}_\mu \rightarrow \bar{\nu}_e \) oscillation channels. While the \( \nu_e \) appearance mode constrains the product of \( |U_{\mu 4}|^2 \) and \( |U_{e 4}|^2 \), the \( \nu_\mu \) and \( \nu_e \) disappearance modes constrain \( |U_{\mu 4}|^2 \) and \( |U_{e 4}|^2 \), respectively.

In summary, we report on a sterile neutrino search based on a minimal extension of the Standard Model, the 3 (active) + 1 (sterile) neutrino mixing model, in the Daya Bay Reactor Antineutrino Experiment using the electron-antineutrino disappearance channel. The analysis used the relative event rate and the spectral comparison of three far and three near antineutrino detectors at different baselines from six nuclear reactors. The data are in good agreement with the 3-neutrino model. The current precision is dominated by statistics. With at least three more years of additional data, the sensitivity to \( \sin^2 2\theta_{13} < 0.1 \text{ eV}^2 \) is expected to improve by a factor of two for most \( \Delta m^2_{41} \) values. The current result already yields the world’s most stringent limits on \( \sin^2 2\theta_{13} \) in the \(|\Delta m^2_{41}| < 0.1 \text{ eV}^2 \) region.

**FIG. 3.** (color online) The exclusion contours for the neutrino oscillation parameters \( \sin^2 2\theta_{14} \) and \( |\Delta m^2_{41}| \). Normal mass hierarchy is assumed for both \( \Delta m^2_{31} \) and \( \Delta m^2_{41} \). The red long-dashed curve represents the 95% C.L. exclusion contour with Feldman-Cousins method [55]. The black solid curve represents the 95% CLs exclusion contour [55]. The parameter-space to the right side of the contours are excluded. For comparison, Bugey’s [32] 90% C.L. limit on \( \nu_e \) disappearance is also shown as the green dashed curve.

The second method was the CLs statistical method [55] described in detail in Ref. [56]. A two-hypothesis test was performed in the \( (\sin^2 2\theta_{14}, |\Delta m^2_{41}|) \) phase space with the null hypothesis \( H_0 \) (3-\( \nu \) model) and the alternative hypothesis \( H_1 \) (3+1-\( \nu \) model with fixed value of \( \sin^2 2\theta_{14} \) and \( |\Delta m^2_{41}| \)). The value of \( \theta_{13} \) was fixed with the best-fit value of the data for each hypothesis. Since both hypotheses have fixed values of \( \sin^2 2\theta_{14} \) and \( |\Delta m^2_{41}| \), their \( \chi^2 \) difference follows a Gaussian distribution. The mean and variance of these Gaussian distributions were calculated from Asimov datasets without statistical or systematic fluctuations, which avoided massive computing. The CLs value is defined by:

\[
\text{CLs} = \frac{1 - p_1}{1 - p_0},
\]

where \( p_0 \) and \( p_1 \) are the p-values for the 3-\( \nu \) and 3+1-\( \nu \) hypotheses models respectively. The condition of \( \text{CLs} \leq 0.05 \) was required to set the 95% CLs exclusion regions.
building the underground laboratory. We are grateful for the ongoing cooperation from the China General Nuclear Power Group and China Light & Power Company.
